Topic of the project: confidence region estimates First semester: one-dimension, i.e. confidence intervals

• in scalar case, the general linear regression model:

$$Y_t = X_t \cdot \vartheta^* + \varepsilon_t \quad (t = 1, \dots, n)$$

- constant in the noise:  $X \equiv 1$
- assumptions on the noise term:
  - independence
  - symmetry
- o confidence intervals:
  - inclusion
  - length

Figure: Example with a uniform(-1;1) sample, n = 30

## The SPS method

#### Advantages:

- mild statistical assumptions
- distribution-free
- non-asymptotic confidence intervals

### Main idea of the SPS:

- introduce sign-perturbed sums  $\{S_i(\vartheta)\}$  and a reference sum  $S_0(\vartheta) \doteq \sum_{t=1}^n \varepsilon_t(\vartheta)$
- construct a confidence interval based on the rank of  $S_0(\vartheta)$

#### Theorem

Assuming the independence and the symmetry about zero of the noise term, the coverage probability of the SPS confidence interval is exactly p, where p is the user-chosen confidence level.

## Simulations

#### Steps of the simulations:

- generate a sample
- construct confidence intervals (50 %), using SPS and a CLT based method
- repeat 10 000 times for n = 10, 20, 30, ..., 100

#### Measurements:

- inclusion rate of the true parameter
- average length of the intervals

## Examined distributions:

- Standard normal
- Mixture of two normal:  $P(X \in \mathcal{N}(m, 1)) = P(X \in \mathcal{N}(m, -1)) = 0.5$  for m = 2, 10, 20
- Student's t with df = 2
- Standard Cauchy
- Symmetrized Pareto with  $\alpha = 2.5, 1.5, 0.5$

Difference w.r.t. regression problems: the output is discrete. In binary case let  $Y_t \in \{0, 1\}$ . No explanatory variable  $\Rightarrow Y_t \sim Ind(\theta^*) \Rightarrow n\bar{Y} \sim Bin(n, \theta^*)$ 

## My simulation:

- $\theta^* = 0.8$
- confidence level = 50 %
- Methods based on
  - SPS
  - CLT
  - binomial distribution (expected to be the best)
